The Patient Health Questionnaire-9 for detection of major depressive disorder in primary care: consequences of current thresholds in a crosssectional study

Nicolaas PA Zuithoff¹, Yvonne Vergouwe¹, Michael King², Irwin Nazareth², Manja J van Wezep¹,³, Karel GM Moons¹, Mirjam I Geerlings¹*

Abstract

Background: There is a need for brief instruments to ascertain the diagnosis of major depressive disorder. In this study, we present the reliability, construct validity and accuracy of the PHQ-9 and PHQ-2 to detect major depressive disorder in primary care.

Methods: Cross-sectional analyses within a large prospective cohort study (PREDICT-NL). Data was collected in seven large general practices in the centre of the Netherlands. 1338 subjects were recruited in the general practice waiting room, irrespective of their presenting complaint. The diagnostic accuracy (the area under the ROC curve and sensitivities and specificities for various thresholds) was calculated against a diagnosis of major depressive disorder determined with the Composite International Diagnostic Interview (CIDI).

Results: The PHQ-9 showed a high degree of internal consistency (ICC = 0.88) and test-retest reliability (correlation = 0.94). With respect to construct validity, it showed a clear association with functional status measurements, sick days and number of consultations. The discriminative ability was good for the PHQ-9 (area under the ROC curve = 0.87, 95% CI: 0.84-0.90) and the PHQ-2 (ROC area = 0.83, 95% CI 0.80-0.87). Sensitivities at the recommended thresholds were 0.49 for the PHQ-9 at a score of 10 and 0.28 for a categorical algorithm. Adjustment of the threshold and the algorithm improved sensitivities to 0.82 and 0.84 respectively but the specificity decreased from 0.95 to 0.82 (threshold) and from 0.98 to 0.81 (algorithm). Similar results were found for the PHQ-2: the recommended threshold of 3 had a sensitivity of 0.42 and lowering the threshold resulted in an improved sensitivity of 0.81.

Conclusion: The PHQ-9 and the PHQ-2 are useful instruments to detect major depressive disorder in primary care, provided a high score is followed by an additional diagnostic work-up. However, often recommended thresholds for the PHQ-9 and the PHQ-2 resulted in many undetected major depressive disorders.

Background

Assessment of major depressive disorder with (semi-)structured interviews such as the CIDI or the SCID [1,2], can be time consuming in the primary care setting. There is a need for using brief instruments such as the Patient Health Questionnaire-9 (PHQ-9) and the PHQ-2 [3], to ascertain the diagnosis of major depressive disorder.

The PHQ-9 is derived from PRIME-MD[4] which was originally developed to detect five common mental disorders in primary care: depression, anxiety, alcohol abuse, somatoform disorder, and eating disorder. It is a self-report questionnaire that assesses the levels of depression on the nine key symptoms (each rated from 0-3) in the past two weeks. The scores on the questionnaire range from 0 to 27: a score of 10 or higher is
indicative of moderate or severe depression and is used
to consider major depressive disorder present[3,5-8].
The score can also be used as a measure of depression
severity[3,9]. A categorical algorithm has also been
developed to determine major depressive disorder with
the PHQ-9[3,9]. The PHQ-2 includes the first two items
of the PHQ-9, ‘any depressed feelings’ and ‘any loss of
interest’[10] and ranges from 0 to 6. In order to detect
major depressive disorder with the PHQ-2, a threshold
of 3 is recommended.

Several studies validated the performance of both
questionnaires in a variety of patient populations, most
of them showing good accuracy[3,5-8,11-16]. However,
the PHQ-9 has not yet been validated in primary care
in the Netherlands. Furthermore, very few studies vali-
dated the accuracy of the PHQ-2[10,12,16,17].

We validated both the PHQ-9 and the PHQ-2 in a
large Dutch primary care patient cohort addressing
three questions: (1) Is the PHQ-9 a reliable and valid
measurement of major depressive disorder in primary
care? Reliability refers to internal consistency as well as
test-retest reliability. Validity refers to construct validity,
i.e. is the PHQ-9 an adequate measurement of depres-
sion severity; 2) Does the threshold score of 10 and the
categorical algorithm for the PHQ-9 yield accurate clas-
sification in primary care?; (3) What is the accuracy of
the PHQ-2 for major depressive disorder in primary
care?

Methods
Patients and design
We used patient data of the PREDICT-NL study, which
is the Dutch part of the PredictD study. The design and
primary results of the PredictD study have been pub-
lished previously[18,19]. In brief, PredictD is a large pro-
spective cohort study that started in 2003 from which a
multifactor risk algorithm was developed for the onset
of major depression over 12 months in primary care in
6 European countries and Chile[18]. Consecutive general
practice patients were asked to participate, irrespective
of their reasons for consulting the general practitioner.
The study was approved by the Medical Ethics commit-
tee of the universities of participating countries.

In the Netherlands, patients were recruited from seven
general practices in the city of Utrecht and surrounding
areas. On random days, research assistants visited the
general practices to recruit patients. Patients aged 18
years or older who visited the general practice were
asked to participate while waiting to see the general
practitioner. Patients interested in participating were
given oral and written information about the study aims
and procedure. If patients were willing to participate,
they received the study information sheet, an informed
consent form, and the questionnaires. The patient was
asked to take the material home, read the study infor-
mation and ask for additional information if necessary.
After having signed the informed consent form they
filled out the questionnaire and returned the signed
informed consent form and questionnaire by regular
mail. Nonresponders were sent a reminder after two
weeks and again after four weeks.

To assess the test-retest reliability of the PHQ-9,
32 consecutively included study participants in
one general practice were asked to fill out the PHQ
questionnaire for a second time after 14 days.

Diagnosis of major depressive disorder (reference
standard)
The diagnosis of major depressive disorder was assessed
in all patients according to DSM-IV criteria[20] by
trained researchers using the depression section of the
Composite International Diagnostic Interview (CIDI)
[21]. When informed consent and the questionnaire
were received, the researchers phoned the participant
and asked the two core questions of the depression sec-
tion of the CIDI interview[21], i.e. did you have a
depressed mood or a loss of interest for a 2-week-period
or longer in the past six months. If the participant
responded negative to both questions a diagnosis of
major depressive disorder was ruled out[20,21]. If the
participant responded positive on one or both questions,
an appointment was made in the general practice to
carry out the full CIDI depression interview to establish
the presence of major depressive disorder. If the partici-

Patient health questionnaire
Each of the nine questions of the PHQ-9 was evaluated
on a 4-point rating scale, ranging from 0 (not at all) to
3 (nearly every day), summing up to a total PHQ-9
score per patient. Major depressive disorder was consid-
ered present if the score was >= 10[3,5-8]. For the categ-
orical algorithm, the answers on the questions were
dichotomized: 0 (not at all) and 1 (several days) are
coded as 0 (symptom absent) and the answers 2 (more
than half the days) and 3 (nearly every day) are coded as
1 (symptom present). The diagnosis of major depressive
disorder is made when at least five symptoms are pre-
sent, and at least one is ‘depressed feelings’ or ‘loss of
interest’[3,20]. For the PREDICT-NL study, the Dutch
version of the PHQ-9 was developed using several steps
of translating and back-translating by researchers and
professional translators, one of whom was a native
English speaker. The PHQ-2 is a reduced version of the PHQ-9: only the core symptoms of major depressive disorder ('depressed feelings' and 'loss of interest'), the first two items, are measured as described above, summing up to a total that ranges from 0 to 6.

**Functional status, sick days, and number of consultations**

We also assessed other parameters to evaluate the validity of the PHQ-9. These were:

1) Functional status using the Medical Outcome Study Short Form General Health Questionnaire-12 (SF-12) [22]. This instrument is divided into scales for mental and physical health, where higher scores indicate better functioning.

2) Information on the number of days in the past 4 weeks that patients were unable to perform usual activities due to health problems (number of sick days).

3) The number of general practice consultations in the past 12 months was counted using the electronic database of the general practitioners. This was assessed as a measure of health service utilisation.

**Data analysis**

We estimated the internal consistency, the degree to which the answers on the individual questions of the PHQ-9 are the same, using intraclass correlations and the test-retest correlation were estimated using Pearson correlations. To assess the validity of the PHQ-9 as a measurement of depression severity, scores were divided in categories of increasing severity: 0-4, 5-9, 10-14, 15-19 and 20 and higher, as used in other studies[3]. Medians and interquartile ranges of the functional status (SF-12), sick days and the number of consultations in the past 12 months were estimated across these categories. Differences between categories were tested with Kruskal-Wallis analysis of variance. Differences in PHQ-9 and PHQ-2 scores between patients with and without major depressive disorder were tested with the Mann-Whitney U test. P-values of 0.05 and lower were considered significant.

We then estimated the concordance-statistic (c-statistic or area under the Receiver Operating Characteristic curve) for the PHQ-9. The sensitivity, specificity, and positive and negative predictive value were estimated for several thresholds of the PHQ-9 overall score and for the categorical algorithm of the PHQ-9. Finally, the c-statistic was constructed for the PHQ-2 and sensitivity, specificity, positive and negative predictive value were calculated for all possible thresholds of the PHQ-2.

The overall percentage of missing values was 9%. As missing data rarely occur at random, it is widely acknowledged that simple deletion of patients with one or more missing values (i.e. complete case analysis) leads to biased results[23-26]. We therefore used single imputation to address missing values. The imputation and analysis was done in SPSS version 15 (SPSS inc. Chicago, Ill).

**Results**

In total, 3089 patients were asked to take part in the PREDICT-NL study, 83 of whom did not meet inclusion criteria, mainly (n = 75) because they had problems understanding the Dutch language. An additional 8 patients were excluded because the general practitioner confirmed that they had dementia (n = 5), psychosis (n = 2), or mental retardation (n = 1). Of the 3006 eligible patients, 1338 (44.5%) gave written informed consent and participated in the study (Figure 1). Reasons for not participating were mostly lack of time and no interest in the study.

The mean age of the study population was 51 years (SD = 16.7), and the majority (63%) was female (Table 1). Thirty five patients (2.6%) consulted the general practitioner for mood related health problems. DSM IV Major depressive disorder according to the CIDI was diagnosed in 176 (13%) patients and was more prevalent in women and younger patients (Table 1). Patients with major depressive disorder had significantly higher scores on the PHQ-9 (p < .000) and PHQ-2 (p < .000) compared with patients without depression.

Thirty-one of the 32 patients approached agreed to fill in the PHQ-9 for a second time. The association between the test and retest scores was excellent, with a correlation of 0.94. The internal consistency of the PHQ-9 was very good with an intraclass correlation of 0.88.

In table 2 the medians of the SF12, the number of sick days and the number of consultations are shown for patients in different PHQ-9 categories. A statistically significant difference in quality of life was observed for patients with different levels of depressive symptoms, with patients with higher levels of depression reporting a lower quality of life. This difference was more pronounced on the mental functioning than the physical functional scale. A statistical significant difference was also observed on the reported number of sick days in the past 4 weeks and number of consultations in the past twelve months (all p-values < 0.001).

The area under the ROC curve of the PHQ-9 was 0.87 (95% CI: 0.84-0.90). Table 3 shows the accuracy measures for different thresholds of the PHQ-9 score. The commonly used threshold of 10 had a specificity of 0.95 but a sensitivity of only 0.49. At a threshold of 6, sensitivity was 0.82 and specificity was 0.82. At this threshold the a-priori probability (prevalence) of 13% was increased to a posterior probability of 41%.

The categorical algorithm of the PHQ-9 showed a specificity of 0.98 and sensitivity of only 0.28. Based on
this we defined an adjusted categorical algorithm to include the responses ‘several days’ as symptom present (see methods), whereas the original algorithm codes these answers as symptom absent. This resulted in a sensitivity of 0.84 and specificity of 0.81, close to those found for a threshold of 6 (Table 3). As the time delay between the PHQ-9 and the reference test varied, we performed an additional analysis to determine the influence of this time delay. Discrimination (area under the ROC curve) was similar when the delay between PHQ-9 and CIDI was longer (results not shown).

The area under the ROC curve of the PHQ-2 was 0.83 (95% CI 0.80-0.87). The commonly used threshold for the PHQ-2 of 3 showed a specificity of 0.94 and sensitivity of 0.42 (Table 3). As with the PHQ-9, lower thresholds showed more balanced values of sensitivity and specificity, notably at a threshold of 2. At this threshold, the a-priori probability (prevalence) of 13% was increased to a posterior probability of 34%.

**Discussion**

The PHQ-9 showed a very good internal consistency and test-retest reliability. Moreover, more severe depressive symptoms as measured by the PHQ were associated with poorer functional status, sick days, and higher number of general practice consultations. The accuracy of detecting major depressive disorder at the recommended threshold of 10 and for the categorical algorithm, however, was poor. Lowering the threshold and minor adjustments of the categorical algorithm showed a considerable improvement of sensitivity, at the cost of lower specificity (Table 3). The adjusted categorical

algorithm included all responses other than ‘Not at all’ as item present. The PHQ-2 showed a similar level of accuracy (i.e. sensitivity and specificity) when a lower threshold of 2 rather than 3 was used.

Our results of the reliability and construct validity of the PHQ-9 are similar to those reported in another primary care study[3] and a study of chronically ill primary care patients[13]. When we compared our observed sensitivities and specificities with other studies, we noted mixed results in the existing literature. A systematic review of the PHQ-9 in primary care found a pooled sensitivity of 0.77 (95% CI: 0.71-0.84) and a pooled specificity of 0.94 (95% CI: 0.90-0.97) for the diagnostic algorithm [15]. Similar results were found for the threshold of 10 in a systematic review by Gilbody et. al. [12]. Both reviews report substantially higher sensitivities compared to those reported here. However, a number of other studies in specific patients populations (e.g. patients with cardiovascular diseases) also observed low sensitivities and comparable specificities as we observed[13,17,27]. Similarly, the recommended threshold of 3 for the PHQ-2 showed a low sensitivity in comparison with other primary care studies[7,10,28], whereas other studies describe results similar to those reported here[16,17,29].

Strengths of this study are, first, that patients were included consecutively on random days, irrespective of their presented symptoms or signs and thus representing all patients in the waiting room of the GP. Second, patients were approached for participation in several general practices in both rural and urban areas to ensure a representative sample. Third, the reference test

was administered by well-trained CIDI interviewers to guarantee the validity of the diagnoses and was applied in all attendees so that there was no selection bias. Fourth, this is the first study that validates the PHQ-9 and PHQ-2 in Dutch primary care.

Our study also has some limitations. First, the non-response rate for this study was relatively high. However, we found very minor non-significant differences in distributions of gender and age compared to responders (data not shown). Second, the prevalence of major depressive disorder in this study was relatively high [30-32]. It is possible that patients with major depressive disorder or similar mood problems were more willing to participate in our study. As a result, we would expect disorders or similar mood problems were more willing to participate in our study. As a result, we would expect that the prevalence of major depressive disorder in this study was relatively high [30-32].

Fourth, this is the first study that validates the PHQ-9 and PHQ-2. Conversely, patients reporting little or no symptoms in the CIDI interview will also report no symptoms on the PHQ-9. As such, this difference in time frame could very easily result in low sensitivities and high specificities for the PHQ-9 threshold and algorithm and the recommended threshold for the PHQ-2.

The currently recommended high thresholds will lead to large numbers of undetected depressions. Before applied in clinical practice, lower threshold values as considered in the present study should be evaluated in other studies with new patients and different settings. The high negative predictive value and a relative low positive predictive value at the lower threshold of 6 (Table 3) showed that exclusion of major depressive disorder is more feasible than inclusion. Even though the positive predicted value of 41% still represents a considerable increase of the a-priori probability of 13%, it also emphasizes the need for a further diagnostic work-up for major depressive disorder in patients with a high score on the PHQ-9.

Conclusion
In conclusion, the results presented here indicate that the PHQ-9 and the PHQ-2 are useful instruments to detect major depressive disorder in primary care. As the positive predictive value is still low, a high score needs to be followed by an additional diagnostic work-up. In addition, the PHQ-9 is a valid measurement of depression severity. For both scales, however, clinicians should be aware that current recommended thresholds could lead to under detection.

Acknowledgements
We thank participating patients for their time and effort. We thank the University Medical Center Utrecht primary care network and its participating general practitioners for their participation in this study. Ethical approval. This study was approved by the Medical Ethics committee of the University Medical Center Utrecht.
